By coupling the bromate−sulfite−ferrocyanide oscillating chemical reaction with the complexation of calcium ion by EDTA, we construct a system that generates periodic pulses of free Ca^{2+} with an amplitude of 2 orders of magnitude and a period of ca. 20 min. These pulses may be observed either with a calcium ion-selective electrode or with Arsenazo(III) as an indicator. We describe the systematic design procedure and the properties of this first abiotic calcium-based chemical oscillator.

Introduction

The concentrations of many elements undergo periodic oscillations in living organisms. Among abiotic chemical systems, either accidentally discovered or deliberately designed,[1] oscillatory behavior has largely been limited to a relatively small number of elements that possess several stable oxidation states: the halogens, sulfur, and a few transition metals.[2] Recently, we developed a systematic design method[3] that makes it possible to incorporate ions of elements with a single stable nonzero oxidation state into oscillatory chemical processes. Our approach is based on coupling a rapid equilibrium (acid−base, complex formation, or precipitation) involving the target element to a known redox-based core or primary oscillator. To a first approximation, if the oscillator is capable of shifting the equilibrium in both directions during the course of its oscillatory cycle, then all species that participate in the equilibrium are driven to oscillate at the frequency of the core oscillator. In many cases, the most convenient choices for the core system and the corresponding equilibrium reaction are a pH oscillator and a pH-dependent equilibrium, respectively.

In choosing an appropriate pH oscillator and the equilibrium reaction to which it is to be coupled in order to generate oscillations in the concentration of a desired species, the following points must be taken into account:

(a) The primary pH oscillator should function over a wide range of pH values. To propel the equilibrium between the reactant- and the product-dominated states, the change in $[H^+]$ during the oscillatory cycle must be sufficiently large.

(b) In addition to being pH-sensitive, the equilibrium reaction must have a moderate equilibrium constant, *K*. If *K* is too large or too small, the variation in the pH will be incapable of shifting the equilibrium back and forth. The system instead will remain in either the "reacted" or the "unreacted" state.

(c) If the components of the equilibrium reaction interact with those of the oscillator to any significant extent, the pH oscillations in the core system may be damped or even eliminated. Anions involved in the equilibrium bind H^+ in proportion to their Lewis basicities. The higher their concentrations and

protonation constants, the stronger the buffering effect that they produce. Cations can also destroy the oscillator if they react (e.g., precipitate) with any of the components of the core reaction.

(d) The change in concentration of the target species in the system must be detectable either visually by the formation and destruction of colored species during the oscillatory cycle or with an appropriate sensor, such as an ion-specific electrode (ISE).

In preliminary experiments, we succeeded in inducing oscillations in the concentrations of Ca^{2+}, Al^{3+}, and F^- ions by coupling pH-dependent equilibria involving these species to a pH oscillator. Calcium oscillations are ubiquitous in biological systems,[4] and therefore building an easily controlled inorganic calcium oscillator is potentially the most significant application of our technique for constructing new oscillators. We present here a detailed study of a new, abiotic calcium ion oscillator.

Experimental Section

Selection of the Subsystems. Our core system consists of the $BrO_3^- - SO_3^{2-} - Fe(CN)_6^{4-}$ (abbreviated as BSF) pH oscillator.[5] Under appropriate conditions in a flow reactor (CSTR), this reaction exhibits oscillations in pH, $[Br^-]$, and redox potential with excellent reproducibility. The measured oscillations in pH lie in the acidic pH range and have a period of 20−30 min. The range of reactant concentrations yielding oscillatory behavior is relatively narrow at room temperature, but significantly wider at higher temperatures. We therefore conducted all of our experiments at 30 °C. From the phase diagrams presented in ref 5, the following input concentrations were chosen as our standard composition (given as concentration in the CSTR after mixing but before any reaction takes place): $[BrO_3^-] = 6.0 \times 10^{-2}$ M, $[SO_3^{2-}] = 7.5 \times 10^{-2}$ M, $[Fe(CN)_6^{4-}] = 2.0 \times 10^{-2}$ M, and $[H_2SO_4] = 1.0 \times 10^{-2}$ M. At a flow rate of $k_0 = 1.45 \times 10^{-3}$ s^{-1} (residence time, 11.5 min), the measured characteristics of the oscillations were $pH_{min} = 2.89$, $pH_{max} = 6.45$, and period = 28 min.

For the calcium-containing equilibrium reaction to be coupled to the BSF system, we chose the complex formation between Ca^{2+} and ethylenediaminetetraacetic acid, disodium salt (EDTA):

$$Ca^{2+} + EDTA^{4-} \leftrightarrow CaEDTA^{2-} \tag{1}$$

Calcium Ion Oscillator

J. Phys. Chem. A, Vol. 110, No. 24, 2006 **7589**

The formation constant of the complex is 5.01×10^{10}. The conditional equilibrium constants calculated at pH 6.0 and 3.0 (roughly the pH_{max} and pH_{min} of the BSF pH oscillator) are $K = 1.13 \times 10^6$ and 1.25, respectively.[6] These data suggest that formation of the CaEDTA complex is almost complete at pH 6.5, but essentially all the Ca^{2+} is free at pH 3.

Thus, the BSF pH oscillator and the formation of the CaEDTA complex, equation 1, constitute a pair of subsystems that fulfill all the selection criteria outlined above.

Materials and Methods

Stock solutions were prepared by dissolving high-quality Aldrich products—$NaBrO_3$, Na_2SO_3, $K_4Fe(CN)_6$, $Na_2H_2EDTA \cdot 2H_2O$ (ethylenediaminetetraacetic acid disodium dihydrate, abbreviated as EDTA), and $CaNa_2EDTA$ (ethylenediaminetetraacetic acid, calcium disodium, abbreviated as CaEDTA)—in deionized water. To ensure good reproducibility in the experiments where $K_4Fe(CN)_6$ and Na_2SO_3 were used, special care was taken in the use and storage of these solutions. Stock solutions of $K_4Fe(CN)_6$ were allowed to stand for at least a day before use and were stored in an amber glass container, in which they were stable for several weeks. Solutions of Na_2SO_3 were found to react reproducibly if they were used no sooner than an hour after preparation and discarded after 3−4 h.

A thermally regulated CSTR was used for the flow experiments. The reactor had a volume of $45.0 \ cm^3$ and operated at 30 °C. No air gap was allowed to form between the surface of the reaction mixture and the Teflon reactor cap. The flow rates employed spanned the range from $k_0 = 2.6 \times 10^{-4}$ to $5.3 \times 10^{-3} \ s^{-1}$. The reagents were introduced into the reactor through four inlet tubes via a Gilson Minipuls 2 peristaltic pump. The concentration of the input solutions was thus 4-fold higher than the reported initial concentrations of the reagents in the reactor. Excess reaction mixture was removed either by overflow or by using a second pump. Three signals were monitored during the experiments. The potentiometric progress of the overall reaction was followed with a $Pt-Hg/Hg_2SO_4/K_2SO_4$ electrode pair. In addition to the redox potential, either the pH or $[Ca^{2+}]$ was simultaneously measured with a combined glass electrode or a Ca^{2+} ISE (Orion 93−20) connected to a double channel recorder through a pH meter. The reaction mixture was stirred, typically at 400 rpm, with a magnetic stirrer using a 2-cm-long, 6-mm-diameter Teflon-coated stirring bar.

To construct the calcium oscillator, the BSF pH oscillator and the components of the $Ca^{2+} + EDTA^{4-} \leftrightarrow CaEDTA^{2-}$ equilibrium were combined in a well-stirred CSTR. We first initiated the pH oscillator by introducing the solutions of $NaBrO_3$, Na_2SO_3, $K_4Fe(CN)_6$, and H_2SO_4 into the reactor. Then the input $NaBrO_3$ solution was replaced with a solution that contained the same concentration of $NaBrO_3$ mixed with CaEDTA.

Results

To find the optimum input concentrations for generating $[Ca^{2+}]$ oscillations in the combined system and to eliminate possible interferences with the response of the Ca−ISE, we had to establish (a) the buffer effect of EDTA on the pH oscillations, (b) the effect of Ca^{2+} on the BSF oscillator, and (c) the influence of the pH and the components of the BSF oscillator on the response of the Ca−ISE.

Buffer Effect of EDTA on the pH Oscillations. Since partially or completely unprotonated EDTA species can bind protons, these species are capable of damping, or even totally suppressing, the pH oscillations in the core system. If the

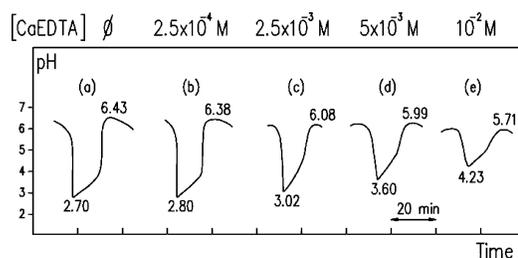

Figure 1. Buffering effect of $EDTA^{4-}$ on pH oscillations in the BSF system (one oscillatory cycle is shown for each CaEDTA concentration). Input concentrations: $[NaBrO_3] = 6.5 \times 10^{-2}$ M, $[Na_2SO_3] = 7.5 \times 10^{-2}$ M, $[K_4Fe(CN)_6] = 2.0 \times 10^{-2}$ M, $[H_2SO_4] = 1.0 \times 10^{-2}$ M, flow rate: $k_0 = 1.45 \times 10^{-3} \ s^{-1}$, $T = 30$ °C, $[CaEDTA] = 0$ M (a), 2.5×10^{-4} M (b), 2.5×10^{-3} M (c), 5.0×10^{-3} M (d), and 1.0×10^{-2} M (e).

concentration of these species becomes too high as a result of the dissociation of CaEDTA at low pH, the pH-driven BSF oscillator may cease to function. To determine the optimum amount of CaEDTA to mix with the BSF system, we measured the oscillatory pH range as a function of added [CaEDTA]. Figure 1 depicts the buffering effect of EDTA released from CaEDTA at low pH values. When [CaEDTA] in the CSTR increases, the amplitudes of both the pH and the redox potential oscillations decrease, and above a critical level of added CaEDTA ($>10^{-2}$ M) no oscillations appear. The "standard composition" BSF pH oscillator maintains an amplitude for $[EDTA^{4-}]$ levels as high as 5×10^{-3} M. Somewhat smaller buffer effects are observed when the EDTA is introduced in the form of Na_2H_2EDTA. From these experiments, we conclude that combining the standard BSF oscillator with 2.5×10^{-3} M CaEDTA yields a system producing high-amplitude Ca^{2+} pulses in the CSTR.

Response of the Ca−ISE to $[Ca^{2+}]$, $[H^+]$, and the Components of the BSF Oscillator. The Ca−ISE used in our experiments showed a linear Nernstian response to $[Ca^{2+}]$ with a slope of 27 mV/decade in the concentration range 10^{-5} M $\leq$ $[Ca^{2+}] \leq 10^{-1}$ M.

The response of the Ca−ISE may also depend on the concentrations of H^+ and the components of the BSF oscillator. We therefore performed a series of measurements to assess the operation of the Ca−ISE in the oscillatory mixture. The responses of Ca−ISE and glass and Pt electrodes were recorded in the presence of 1.0×10^{-3} to 2.5×10^{-3} M Ca^{2+} (as $CaCl_2$) in the BSF oscillatory mixture. The Ca−ISE gives a nearly constant signal, whereas the glass and Pt electrodes respond in an oscillatory manner without noticeable changes in the amplitude and frequency from the values found in the Ca^{2+}-free system. These results demonstrate that (i) changes in pH between 3 and 6.5 have almost no effect on the response of the Ca−ISE (e.g., the potential of the Ca−ISE measured with $[Ca^{2+}]$ = 10^{-3} M at pH 3 and 6.5 differed by only 3 mV), (ii) the components of the BSF system do not interfere with the functioning of the Ca−ISE, and (iii) Ca^{2+} ions do not disturb the oscillatory behavior of the BSF mixture.

Ca^{2+} Pulses Induced by the BSF Oscillator. Figure 2 shows the oscillatory changes in pH, redox potential, and potential of the Ca−ISE recorded simultaneously in the CSTR when a mixture of the standard BSF oscillator and $[CaEDTA] = 2.5 \times 10^{-3}$ M, our estimated optimum concentration, are introduced. As seen in Figure 2a,c, the pH oscillations induce a relatively large (2 orders of magnitude) variation in the concentration of free calcium ions, which appear in pulses in this combined system. Figure 3 shows how the electrode responses seen in Figure 2 are modified when the input feed of $NaBrO_3$ +

**Figure 2.** Oscillations in pH (a), redox potential (b), and potential of a Ca−ISE (c) in the BSF−CaEDTA system. [CaEDTA] = 2.5×10^{-3} M. All other parameters as in Figure 1.

CaEDTA is replaced with $NaBrO_3$. The Ca−ISE signal dies away completely as CaEDTA is washed out of the CSTR by the flow of BrO_3^-. The oscillations in [Ca^{2+}] are restored and then cease again within 4−5 residence times when the renewal and removal of the CaEDTA input are repeated. The small

increases in the amplitude of the pH (Figure 3a) and Pt (Figure 3b) oscillations and in the length of the period are due to removal of the buffering species, the ligand EDTA. In separate experiments, the input $NaBrO_3$ + CaEDTA solution is replaced with $NaBrO_3$ + Na_2EDTA. Here the trace of the Ca−ISE damps exactly as in Figure 3c, but the pH and Pt electrodes respond as in Figure 2a,b.

To establish the upper and lower limits of [CaEDTA] in the CSTR that permit Ca^{2+} oscillations, we measured the response of the Ca−ISE over a range of input [CaEDTA] with the standard BSF oscillator. With [CaEDTA] = 2.5×10^{-5}, 2.5×10^{-4}, 2.5×10^{-3}, 5.0×10^{-3}, and 1.0×10^{-2} M, the Ca−ISE gives oscillatory responses with amplitudes of 18, 36, 50, 51, and 20 mV, respectively. These data enable us to establish the optimum [CaEDTA] in the BSF−EDTA system as 2.5×10^{-3} to 5×10^{-3} M under our experimental conditions. At low values of [CaEDTA], increasing [CaEDTA] results in a larger amplitude of Ca^{2+} oscillation, but as [CaEDTA] rises the stronger buffering effect attenuates, and eventually shuts down the pH oscillations in the core system, thereby suppressing the Ca^{2+} oscillations as well.

The shape of the oscillatory Ca−ISE signal also changes as [CaEDTA] is varied. Figure 4 shows the oscillations in the Ca−ISE potential when the input [CaEDTA] in Figure 2 is halved. The near-sinusoidal shape seen in Figure 2c becomes more rectangular as [CaEDTA] is lowered.

The behavior of the system is also sensitive to the flow rate k_0. We examined the BSF−CaEDTA system at [CaEDTA] = 5×10^{-3} M over a range of flow rates. When the CSTR was filled with the reagents at our maximum flow rate, $k_0 = 5.3 \times 10^{-3}$ s^{-1}, and this flow rate was maintained, a high pH (5.94) steady state associated with a steady low free [Ca^{2+}] was found. When k_0 was decreased to 2.0×10^{-3} s^{-1}, high amplitude (52 mV) oscillations in the signal of the Ca−ISE were recorded with a sharp peak at the upper part of the oscillatory traces. Oscillations with $k_0 = 1.45 \times 10^{-3}$ s^{-1} (our "standard" flow rate) are shown Figure 2c. When k_0 was further decreased to 1.0×10^{-3} s^{-1}, the oscillatory state was converted to a low pH (4.2) steady state with a high free [Ca^{2+}].

Bistability is commonly associated with chemical oscillators in a CSTR.[1] In the core BSF system at 20 °C, a wide range of hysteresis was observed in the pH as a function of flow rate.[5] At a composition in the bistable domain of the pH vs k_0 phase diagram of the BSF oscillator, we found hysteresis in the presence of 10^{-3} M CaEDTA at 20 °C. The results shown in Figure 5 indicate that the bistability associated with the BFS system is preserved and induces two steady states in [Ca^{2+}]. At high flow rates the pH remains high (~6.4) due to the low extent of the reaction in the core oscillator, and consequently the free [Ca^{2+}] is low. This state, designated as SS I in the figure, is transformed to a low pH−high [Ca^{2+}] steady state (SS II)

Calcium Ion Oscillator

when k_0 is decreased below 4×10^{-3} s^{-1}. On increasing the flow rate, the reverse transition occurs at $k_0 = 9 \times 10^{-3}$ s^{-1}. Between the two transition points the system can be shifted between SS I and SS II by applying acidic or basic perturbations. The threshold pH is about 5. If pH > 5 or pH < 5 is reached in the CSTR after perturbation, the system evolves to the low $[Ca^{2+}]$ or the high $[Ca^{2+}]$ steady state, respectively.

Visualizing the Ca^{2+} Pulses. The BSF−CaEDTA system undergoes oscillations in electrochemical potential (e.g., signals of Pt, glass electrodes, and Ca−ISE) without observable color

changes. Since we are interested in observing spatial pattern formation as well as temporal oscillation in calcium oscillators, we sought an indicator that makes the oscillations in $[Ca^{2+}]$ visible. Examples of such pattern formation include traveling spiral waves[7] and stationary Turing structures[8] in the Belousov−Zhabotinsky (BZ) and chlorite−iodide−malonic acid (CIMA) chemical systems, respectively, and Ca^{2+} spiral waves observed in developing frog oocytes.[9]

Periodic changes in color may occur in a chemical oscillator as a result of formation of a colored intermediate (e.g., in many uncatalyzed bromate oscillators[10]), generation of a colored complex acting as a catalyst (e.g., ferroin in the BZ oscillator[11]), or the use of indicators for an oscillating species (e.g., starch for iodine in the CIMA reaction[8]). In the BSF−CaEDTA system, the solution is pale yellow due to the presence of $Fe(CN)_6^{4-}$ and $Fe(CN)_6^{3-}$. Oscillations in the free $[Ca^{2+}]$ can be visualized by adding Arsenazo(III) dye to the input solution of BrO_3^- and CaEDTA. The dye forms a blue 1:1 complex with Ca^{2+} ($\lambda_{max} = 655$ nm), while the free ligand is pink or cherry red depending on its concentration.[12] Since the color of the dye may also depend on the pH, we examined the behavior of the indicator in the BSF oscillatory mixture. In the presence of Arsenazo-(III) but in the absence of CaEDTA, no changes in the red color occur in the BSF system during the pH and redox potential oscillations. If CaEDTA is also present, periodic color changes are observed. At low pH (high free $[Ca^{2+}]$) the reaction mixture is violet, corresponding to formation of the Ca^{2+}−Arsenazo-(III) complex. At high pH (low free $[Ca^{2+}]$), the solution is cherry red, the color of free Arsenazo(III). The bistable BSF−CaEDTA−Arsenazo(III) system is red in SSI and violet in SSII.

These color changes observed in the bistable or the oscillatory BSS−CaEDTA reaction are not as dramatic as in some other systems that produce patterns in thin solution layers. We are therefore continuing our efforts to find better dyes (e.g., fluorophores) to visualize the changes in $[Ca^{2+}]$ that occur in the BSF−CaEDTA system.

Discussion

We have produced, recorded, and visualized oscillations in the concentration of free calcium ions by combining two independent subsystems, the BSF pH oscillator and the complex

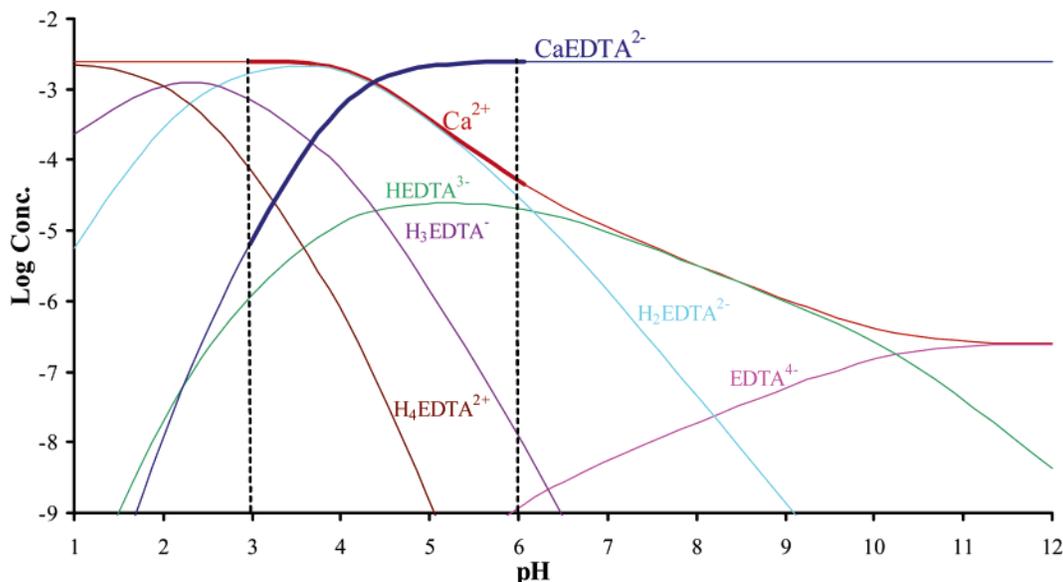

Figure 6. Distribution of species in the Ca^{2+} + EDTA^{4-} ↔ CaEDTA^{2-} equilibrium as a function of pH calculated at $[Ca^{2+}]_{TOT} = [EDTA]_{TOT} = 2.50$ mM.

Kurin-Csörgei et al.

formation equilibrium between Ca^{2+} and EDTA. The dynamical behavior of the combined system is determined by the properties of both subsystems. In this work, our goal was to induce large amplitude oscillations in the response of a Ca–ISE. Therefore, the two subsystems were tuned to generate large oscillatory changes in $[Ca^{2+}]$. The mixture of the standard BSF oscillator and $[CaEDTA] = 2.5 \times 10^{-3}$ M was found to represent such an optimal system.

The distribution of all species that participate in the Ca^{2+} + EDTA $\leftrightarrow$ CaEDTA equilibrium was calculated as a function of pH using the MEDUSA software package[13] at initial concentrations $[Ca^{2+}] = [EDTA] = 2.5 \times 10^{-3}$ M (with the protonation constants of EDTA and the formation constant of CaEDTA taken from ref 6). The results are shown in Figure 6. At pH 3 and 6 (the pH_{min} and pH_{max} in the core oscillator at $[CaEDTA] = 2.5 \times 10^{-3}$ M), the calculated free $[Ca^{2+}]$ is 1.0×10^{-5} M and 2.4×10^{-3} M, respectively. The amplitude of potential oscillation of the Ca–ISE measured in the combined system under the same experimental conditions is 51 mV (Figure 2c), which, using the Nernst equation and our observed 27 mV/decade response, corresponds to almost a 100-fold change of $[Ca^{2+}]$ at 30 °C.

The encouraging agreement between the measured and calculated changes in $[Ca^{2+}]$ during the oscillatory cycle demonstrates that reactions that produce pulses of otherwise nonoscillatory species can be designed by the method described in ref 3. Using other oscillators and other acid–base, complexation, or precipitation equilibria, it should be possible to generate periodically varying concentrations of many free metal ions or anions, including species such as Zn^{2+}, Al^{3+}, Ba^{2+}, or F^-, which are not capable of participating as reagents in redox chemistry-based chemical oscillators. Ultimately, we hope to be able to utilize these new chemical oscillators for applications such as pattern formation, modulating the structure of ion-sensitive hydrogels, and coupling to biological systems, though achieving the last goal will require addressing issues of biocompatibility as well.
